Abstract: The effect of a short gustatory signal of a sweet solution was tested on 15 young male volunteers. The experiment consisted of mouth rinsing with either a sucrose or aspartate solution or pure water as a placebo. Blood was then taken in short intervals of 0, 5, 10, 15 and 20 min. Blood glucose, C-peptide, insulin and cortisol were determined. While C-peptide and glucose were unaffected, a short-term increase in insulin was observed after the sucrose, but not after the aspartate or placebo. The increase in insulin was significant, though it amounted to only 0.5 mIU/l and lasted approx. 15 min reaching then the starting value. The decline of cortisol level within 20 min of the experiment was approx. 40 nmol/l, although it was also observed after aspartate or placebo mouth rinsing and was probably caused by stress factors or anticipation. In conclusion, the contribution of taste to the cephalic phase of insulin secretion is small yet significant, and mouth rinsing with 5% sucrose causes an insulin increase of just under 1 IU/l, which returns to starting level within 15 min.

Introduction
Secretion of insulin by beta-cells of the islets of Langerhans is a very complex
dynamic process that includes basal and stimulated insulin secretion. Two phases,
one early and one late, can be distinguished in insulin secretion initiated by
various stimuli. The early phase is characterised by the secretion of preformed
insulin granules, lasts about 15 minutes and is formed by cephalic (Berthoud et al.,
1981; Ahrén and Holst, 2001; Gautam et al., 2006) and gastrointestinal components.

The cephalic phase of insulin secretion starts by stimulating visual, olfactory
and taste receptors (Berthoud et al., 1981; Ahrén and Holst, 2001; D'Alessio
et al., 2001) and therefore is not only a part of the first steps of food ingestion,
but also of anticipatory physiological regulation in feeding (Power and Schulkin,
2008). Though taste is a very important factor for appetite and food intake, its
separate role in the secretion of hormones taking part in glucose homeostasis has
not been studied much in detail until now. The quantitative contribution of taste to
changes in circulating hormonal levels in humans is, in particular, unknown.

The role of the gustatory system on glucose homeostasis in humans was
documented mainly postingestively on intestinal taste receptors (Maillet, 2011;
Merigo et al., 2011; Shirazi-Beechey et al., 2011; Geraedts et al., 2012). The study
of Joosten et al. (2010) sought to determine whether short oral alcohol exposure,
in the form of white wine, provokes cephalic phase responses. The exposure
transiently lowered serum free fatty acids. Another study investigated the changes
in athletic performance after oral carbohydrate sensing. Simple tasting (mouth
rinsing) with saccharides had the same effect on increasing performance as the
ingestion of a beverage (Jeukendrup and Chambers, 2010).

The aim of the present study is to show to what extent the concentrations
of insulin, C-peptide and cortisol are changed by a simple mouth rinsing with
a sucrose or sweetener solution.

Material and Methods
Subjects
15 non-obese voluntary male participants aged 20–30 years were included
in the study. Their average age was 28.8 ± 6.32 years, BMI 23.43 ± 1.71 kg/m^2.
Men were randomly selected in three groups. In the first group, the tests were
carried out in the sequence sugar – sweetener – water; in the second in the
sequence placebo – sweetener – sugar and, in the third, water – sugar – sweetener.
A 5% sucrose and 0.018% aspartate solution was used for the sweet solution. Tap
water was used as a placebo. The study was improved by the Ethical Committee of
the Institute of Endocrinology and all participants signed the informed consent.

The experiment started at 8 a.m.; the overnight-fasting volunteers were laid
down and their forearm veins were cannulated and, following 15 min of rest, the
zero-time blood withdrawal was carried out. The first mouth rinsing then started
with blood withdrawals at 5, 10, 15 and 20 min. A 10-min pause was followed by

the next rinsing. Serum was separated and glucose, insulin, C-peptide and cortisol were determined in all samples.

Analytical methods

Blood glucose was measured using the enzymatic reference method with hexokinase (analyzer Cobas Integra 400 plus, Roche). The measuring range of the kit was 0.12–40 mmol/l. Intra- and inter-set reproducibility was 1.7% and 2.6%, respectively.

C-peptide was measured using ECLIA (electrochemiluminescence immunoassay, analyzer Modular E 170, Roche). The measuring range of the kit (defined by the lower detection limit and the maximum of the master curve) was 0.003–13.3 nmol/l for plasma. Intra- and inter-assay coefficient of variation was 1.5% and 2.3%, respectively.

Insulin was measured using ECLIA (electrochemiluminescence immunoassay, analyzer Modular E 170, Roche). The measuring range of the kit (defined by the lower detection limit and the maximum of the master curve) was 0.2–1,000 IU/ml. Cortisol was assayed using a RIA kit from Orion, Finland (intra-assay CV = 3.8%, inter-assay CV = 4.4%).

Statistical data analysis

Repeated measures ANOVA with subject factor and within-subject factor Time was used to evaluate the differences between the experiment stages followed by least significant difference (LSD) multiple comparisons. The original dependent variables and the covariate were transformed by a power transformation to attain a constant variance and symmetric distribution of the data and residuals (Meloun et al., 2000). Statistical software Statgraphic Centurion version XVI (Herndon, VA, USA) was used for the calculations. The homogeneity of the data and residual were checked as described elsewhere (Meloun et al., 2002).

Results

To prove effect of mouth rinsing with water and sugar or sweetener solutions, the time course analysis by ANOVA was decisive (see: Time in Figures 1–4).

Oral stimulation by rinsing mouth with a 5% sucrose solution caused a slight but significant rise in insulin level in circulating blood (Figure 1) over the course of 5–10 minutes and then returned to the basal level. No change in glucose and C-peptide levels were observed (Figures 2 and 3). Sucrose rinsing also caused a distinct drop in cortisol level, though this effect was observed also with the sweetener and placebo (Figure 4). This probably indicates an unspecific effect.

Less pronounced changes in insulin concentration caused by the sweetener (aspartate) solution in an organoleptic concentration similar to the sucrose solution were insignificant. Aspartate decreased significantly the time course of C-peptide (Figure 3).

The placebo (water) had no effect on circulating insulin or C-peptide concentrations.

Figure 1 – Changes of insulin after stimulation with sugar, sweetening agent, and without the stimulation evaluated by repeated measures ANOVA consisting of subject factor and a within-subject factor Time and followed by a least significant difference multiple comparisons. Circles, squares, and triangles with error bars represent mean values with their 95% confidence intervals for sugar, sweetening agent, and no stimulation, respectively. Statistics for individual stimulations are as follows:

Sugar stimulation: R^2=94.5%, p<0.0001; Time: F=2.26, p=0.0741; Subj.: F=66.37, p<0.0001

Sweetening agent stimulation: R^2=88.2%, p<0.0001; Time: F=0.61, p=0.6555; Subj.: F=29.66, p<0.0001

Placebo (water): R^2=87.2%, p<0.0001; Time: F=1.75, p=0.1605; Subj.: F=24.01, p<0.0001

R^2, F, and p represent the % of the total variability in dependent variable explained by the ANOVA model, F-ratio, and p-level, respectively.

Discussion

Attention was recently paid to glucose sensing and signalling in the post-ingestive phase and to the regulation of intestinal glucose transport (Maillet, 2011; Shirazi-Beechey et al., 2011; Geraedts et al., 2012). In this respect the lingual tasting system warranted less attention, though the presence of various hormones (Martin et al., 2009) and glucose transporters (Merigo, 2011) was demonstrated in taste receptor cells. The presence of glucagon-like peptide GLP-1 in taste cells type II and III highlights in particular a parallel between gustatory and intestinal epithelia (Martin et al., 2009).

The cephalic phase of insulin secretion is commonly ascribed to the complex signals from the visual, gustatory and olfactory system together with anticipation based on previous experience. In the present study, we try to show that the signalling by isolated gustatory perception of sweet taste contributes significantly, though only in a small extent and briefly. Such effect lasts only minutes, similarly as in the experiments with short oral white wine exposure (Joosten et al., 2010), which provoked transient decrease of serum free fatty acids. It should be mentioned that liquids and chewing gum do not provide adequate stimulation for vagal efferent activation of nutrient metabolism in humans and that mixed nutrient foods are the optimal stimuli (Teff, 2010). The effect of insulin increase induced by taste sensing as a part of cephalic phase is far less intensive than stimulation of insulin secretion by gastrointestinal regulatory factors in the later acute phase of insulin secretion. There is a discrepancy between increase of insulin after sweet sensing and permanent levels of C-peptide, suggesting a mobilisation of insulin from preformed granules.

The present study showed nearly constant glucose and C-peptide level during the experiment, a short insulin increase after sucrose signal and a decrease of the cortisol concentration, which, however, was also observed after placebo exposure. We tried to eliminate the effect of cortisol daily rhythm by changing the sequence of application of the three signals (sugar – sweetener – water); some effect could be expected as consequence of cannulation (Šimůnková et al., 2010), but, despite this, we are not able to explain the cortisol decrease fully.

Our results are in agreement with the experience that in comparison with sucrose, sweeteners are metabolically less active (Pepino and Bourne, 2011).

In conclusion, the contribution of taste to the cephalic phase of insulin secretion is small yet significant, and mouth rinsing with 5% sucrose causes an insulin increase of just under 1 mIU/l, which returns to starting level within 15 min.
